ABSTRACT
As GPU's compute capabilities grow, their memory hierarchy increasingly becomes a bottleneck. Current GPU memory hierarchies use coarse-grained memory accesses to exploit spatial locality, maximize peak bandwidth, simplify control, and reduce cache meta-data storage. These coarse-grained memory accesses, however, are a poor match for emerging GPU applications with irregular control flow and memory access patterns. Meanwhile, the massive multi-threading of GPUs and the simplicity of their cache hierarchies make CPU-specific memory system enhancements ineffective for improving the performance of irregular GPU applications. We design and evaluate a locality-aware memory hierarchy for throughput processors, such as GPUs. Our proposed design retains the advantages of coarse-grained accesses for spatially and temporally local programs while permitting selective fine-grained access to memory. By adaptively adjusting the access granularity, memory bandwidth and energy are reduced for data with low spatial/temporal locality without wasting control overheads or prefetching potential for data with high spatial locality. As such, our locality-aware memory hierarchy improves GPU performance, energy-efficiency, and memory throughput for a large range of applications.

Categories and Subject Descriptors
C.1.2 [Multiple Data Stream Architectures]: Single-instruction-stream, multiple-data-stream processors (SIMD)

General Terms
Design, Experimentation, Performance

Keywords
GPU, SIMD, SIMT, Fine-Grained Memory Access, Irregular Memory Access Patterns, Adaptive Granularity Memory

1. INTRODUCTION
General purpose computation with graphics processing units (GPUs) has become increasingly popular thanks to the high compute throughput and peak memory bandwidth of these devices. A coarse-grained (CG) memory hierarchy enables GPUs to exploit programs with high spatial locality, increasing peak memory bandwidth and decreasing control overheads. Regularly structured, compute-intensive applications can readily utilize the high peak memory bandwidth and ample computational resources of GPUs to great effect. However, not all applications can be re-factored to exhibit regular control flow and memory access patterns, and many emerging GPU applications suffer from inefficient utilization of off-chip bandwidth and compute resources [1, 2, 3]. Recent proposals have primarily focused on overcoming irregularity by improving device utilization and latency tolerance [4, 5, 6, 7, 8, 9, 10, 11, 12, 13, 14, 15], but the memory bandwidth bottleneck still remains as a significant issue in future throughput computing [16].

Coarse-grained memory accesses waste off-chip bandwidth and limit the energy-efficiency of current GPUs for irregular applications by over-fetching unnecessary data. Figure 1 shows the number of 32-byte sectors (out of each 128-byte cache block) that are actually referenced over the lifetime of L1/L2 cache blocks. Regularly structured programs with high spatial and temporal locality use most or all of the sectors within each cache block, effectively utilizing the CG memory accesses of the current GPU memory hierarchy. As we study in this paper, however, the massively multithreaded nature of GPUs allows little cache capacity per thread, resulting in high cache miss rates and reducing the amount of temporal locality that can be exploited for certain applications. Such behavior (combined with the CG-only memory hierarchy) significantly over-fetches off-chip data for irregular applications, wasting memory bandwidth, on-chip storage, and DRAM power.

This paper presents the first memory hierarchy design that can efficiently handle irregular memory access patterns and scatter-gather programs in modern GPU architectures. We design a reactive and efficient memory system that is locality-aware such that it can cater to the behavior of irregular GPU programs. Prior work has used the dynamic estimation of spatial data locality for selective fine-grained (FG) memory accesses in control-intensive, general-purpose CMP environments [17, 18]. We show that such approaches, while successful for CPUs, fall short for massively multithreaded throughput-oriented GPUs because many emerging GPU applications with irregular control/memory accesses exhibit low temporal locality and caching efficiency. To this end,

This is the author version of the work. It is posted here by permission of ACM for your personal use. Not for redistribution. The definitive version was published in the Proceedings of MICRO-46 December 9–11, Davis, CA, USA.

1 A coarse-grained memory hierarchy is currently assumed to be part of the baseline GPU design in the academic community (Section 2.2).
We then develop a scalable, low-cost hardware predictor with each core containing a number of SIMD lanes for vector width, energy-efficiency, and overall performance. Also, the processor (SM) in NVIDIA’s CUDA terminology; we share this terminology throughout the rest of this paper.

2. BACKGROUND

2.1 CUDA Programming Model

Current GPUs [19, 20, 21] consist of multiple shader cores\(^2\), with each core containing a number of SIMD lanes for vector instructions. In NVIDIA’s CUDA programming model, scalar threads are grouped into thread blocks that execute a single program (or kernel). To facilitate the execution of scalar threads in the SIMD pipeline, the thread scheduler coordinates the issue/execution of threads at a warp granularity; currently, a warp is defined as a group of 32 threads executing in lockstep. Because current GPUs are built around the single-instruction multiple-thread (SIMT) model [22, 23], each SIMD lane can execute its own logical thread with hardware support for independent branching and load/store instructions. This native support for diverging scalar threads allows memory accesses to exhibit fine-grained scatter-gather characteristics, as memory addresses are determined at a per-thread granularity. This means a warp can generate up to 32 independent memory transactions. To reduce the control overheads of a memory operation, GPUs contain a memory-coalescing unit that agglomerates the memory requests of active threads within each warp, whose requesting data size can ranges from 32 to 128-byte.

While FG memory accesses are allowed by the programming model, current GPU memory system is ill-suited for efficient execution of such workloads. Rather, the GPU memory system is optimized for CG accesses, as described below.

2.2 Coarse-Grained GPU Memory Systems

GPU manufacturers do not reveal deep microarchitectural details of their memory systems, so previous literature [8, 10, 11, 12, 15] assumes a baseline GPU memory system optimized for CG memory accesses (Figure 2). This is based on the fact that each memory-channel of Fermi (GF110, [19]), Kepler (GK110, [20]), and SouthernIslands [21] are 64-bits, making a 64-byte minimum-access granularity (8-bursts, 64-bits per burst) with GDDR5 chips [24]. Following memory coalescing, accordingly, the off-chip memory system of GPUs presents a uniform interface to the processor with a large minimum access granularity of cache block size, as shown in Figure 2.

2.3 Fine-Grained Data Management

Coarse-grained accesses can be useful, as they reduce miss rates and amortize control costs for spatially and temporally local requests. Emerging applications, however, exhibit dynamic and heterogeneous amounts of spatial locality, and the massively-multithreaded GPU architecture limits the temporal locality that can be exploited. In the absence of
high locality, FG memory accesses avoid unnecessary data transfers, save power, and improve system performance. Section 2.3.1 and Section 2.3.2 introduce key microarchitectural structures that are adopted by this work to enable the FG management and storage of data.

2.3.1 Sub-ranked Memory

A conventional GPU memory system uses multiple DRAM chips organized in a rank to provide coarse-grained accesses to memory. In order to exploit the benefits of FG accesses for irregular workloads, LAMAR must reduce the minimum access granularity to off-chip memory. To do so, LAMAR leverages a sub-ranked memory system to non-intrusively allow fine-grained memory requests. The sub-ranked memory system adopted by LAMAR is inspired by many prior works, including HP’s MC-DIMM (multi-core dual in-line memory module) [25, 26], Rambus’s micro-threading [27] and threaded memory module [28], the mini-rank memory system [29], and Convey’s S/G DIMM (scatter/gather dual in-line memory module) [30]. In a sub-ranked DIMM, peripheral circuitry is used to divert memory command signals to a sub-rank of DRAM chips without changing the DRAM structure itself. Figure 3 shows the sub-ranked memory system used for LAMAR, which provides a minimum access granularity of 32-bytes, equivalent to the smallest data request generated by an SM [22]. Because LAMAR provides an adaptive access granularity to suit program needs, CG memory requests are also allowed—with sub-ranking disabled, CG memory requests proceed as normal.

2.3.2 Fine-Grained Cache Architecture

Fine-grained memory accesses require some cache changes to maintain FG information in the on-chip memory hierarchy. This work utilizes a simple sector cache [31] to enable the on-chip management and storage of FG data. The sector cache partitions each cache block into sectors, each with its own validity meta-data; this allows for data to be managed at a granularity finer than a cache block. Figure 3 illustrates how data are partitioned and stored into a sectored cache block. The sector cache used for LAMAR partitions each cache block into 4 32-byte sectors.

2.4 Related Works

Prior work uses programmer-annotated [17, 32] or dynamically estimated [18] spatial locality data for multi-granularity memory accesses in a control-intensive, general-purpose CMP environment. This study demonstrates that these adaptive-granularity memory systems fall short for throughput processors, as they lack consideration for massive multithreading.

As was previously mentioned, CG-only memory systems inefficiently utilize off-chip bandwidth in the presence of program irregularity. As such, high-end vector processors (such as Cray’s Black Widow [33]) sometimes use a FG-only memory system approach to good effect. However, such systems squander the benefits of CG accesses for programs with ample locality. It is unlikely that a FG-only approach would be competitive in the GPU market, where the performance of regular graphics workloads is of paramount importance.

3. LOCALITY-AWARE MEMORY SYSTEM

This work is motivated by the dual observations that many GPU applications demonstrate highly dynamic and heterogeneous amounts of spatial locality, and that the low per-thread cache capacity of throughput processors limits the amount of temporal locality that can be exploited by running programs. With a CG-only memory system, these factors conspire to squander off-chip memory bandwidth and energy by over-fetching unnecessary data (Figure 1). Established techniques estimate and exploit the spatial locality of cache blocks in multi-core CMPs to deal with a similar phenomenon [17, 18, 34, 35]. However, as we demonstrate, these prior techniques do not provide robust benefits for all GPU applications because they do not consider the temporal locality of data. We make
the case for a locality-aware memory hierarchy (LAMAR) that provides robust, effective multi-granularity access for throughput processing.

3.1 High-Level Overview of LAMAR

LAMAR uses a sector cache (both L1 and L2) and a sub-ranked memory system\(^3\) in order to demonstrate the full benefits of our proposed scheme (Figure 4). The width of each sector, as well as the minimum access granularity of the sub-ranked memory system, is equivalent to the smallest data request size generated by the memory-coalescing unit within the SM, which in current generation of GPUs is 32-bytes (Section 2.1)\(^4\). Each cache is augmented with a granularity decision unit (GDU) that determines the access granularity of each cache miss. In the baseline CG-only memory system, all cache misses are requested at a cache block granularity, whereas LAMAR leverages the GDU to determine which access granularity best suits the application.

3.2 Statically-Driven GDU

LAMAR provides the programmer the option to tune the access granularity by statically designating whether to fetch all program data at a coarse or fine granularity. Such a decision may be guided by profilers/autotuners and is sent to the runtime system (e.g., through compiler options, APIs, etc.) to update each GDU. Skilled programmers can therefore configure the GDU as appropriate to the application’s needs, achieving optimal bandwidth utilization and energy-efficiency. As detailed in Section 5, we find the average number of sectors referenced within a cache block (Table 3, Avg\(_{sec}\)) to be a good metric for characterizing the program access granularity.

3.3 Dynamically Adaptive GDU

Despite the advantages of a statically-driven GDU, identifying and specifying the optimal access granularity requires both extra effort from the programmer and system support. To this end, we describe a hardware-only mechanism that dynamically derives the optimal access granularity at runtime, achieving comparable benefits of the statically-driven GDU in a robust manner across all studied applications.

3.3.1 Spatial-Pattern Predictor

Previous work exploits adaptive granularity memory accesses in a multi-core CMP system [18] using a spatial-pattern predictor [34, 35] (SPP) in place of the GDU. Spatial pattern prediction uses a pattern history table (PHT) to collect and predict likely-to-be-used sectors upon a cache miss. Each cache block in an SPP-based system is augmented with a set of used bits that designate whether a given sector has been referenced or not. When a cache block is evicted, the corresponding used bit information is committed to the PHT. Future misses to each block query the PHT to determine which sectors are likely to be referenced in the future, allowing targeted sector fetches. Details of the microarchitectural aspects of the SPP can be found in [18, 35].

3.3.2 Pitfalls of SPP-based GDU in GPUs

While spatial pattern prediction has been effectively employed in multi-core CMP research, we explain in this section why the SPP does not perform well in the massively multithreaded GPU environment. As pointed out in previous literature [10, 36], many GPU applications do not cache well and suffer from high cache miss rates and low block reuse. Such low caching efficiency occurs both due to streaming data accesses and also because the threads contend for cache resources and constrain the effective on-chip storage available to each thread. While massive multithreading enables GPUs to be highly latency tolerant, it comes at the cost of poor cache performance, which (combined with the CG-only memory system) wastes memory bandwidth and can limit system energy-efficiency.

The SPP is not as effective for multi-granularity access in GPUs as it is in CMPs, because the high cache turnover rate and low cache block reuse of GPUs significantly lowers the temporal locality that can be exploited by the on-chip memory hierarchy. Figure 5 shows the distribution of repeated accesses across all cache blocks in the baseline memory system. 12 of the 20 benchmarks suffer from poor cache block reuse due to low temporal locality and high on-chip storage contention, resulting in more than 50% of the L2 cache blocks never being reused before eviction. While the SPP accurately estimates the spatial locality of data, it is not robust in the presence of low temporal locality and poor cache performance.

---

\(^3\)We also discuss the implications of LAMAR with minimum changes to the GPU architecture by only using a sectored L1/L2 cache without a sub-ranked memory system, the result of which is detailed in Section 5.5.

\(^4\)Enabling a minimum access granularity smaller than 32-bytes requires restructuring the memory-coalescing unit in the SM. In this work, we leverage the current SM architecture as-is to demonstrate the benefits of LAMAR while minimizing the changes to the current GPU architecture.
as we quantitatively demonstrate in Section 5.1.

3.4 Bi-Modal Granularity Predictor

In general, we observe that the SPP fails to provide robust prediction quality and high energy-efficiency to a wide range of GPU applications. While a more sophisticated prediction algorithm could potentially enhance the effectiveness of SPP, the complexity and high area overhead of a modified SPP will not scale to a many-core environment. We propose a simple, low cost bi-modal granularity predictor (BGP) that is much more suitable for throughput-oriented architectures.

3.4.1 Key Idea and Observation

The main inefficiency of spatial pattern prediction is that the spatial locality information tracked by the PHT is useless for cache blocks with low temporal locality. With this in mind, our proposed BGP microarchitecture is structured such that it estimates both the temporal and spatial locality of missed cache blocks and determines whether to fetch all of the sectors within the cache block (CG-mode) or only the sectors that are requested (FG-mode). The key observation behind BGP is that for cache blocks with poor temporal locality, it is sufficient to fetch only the sectors that are actually requested (on-demand) because the other sectors will most likely not be referenced during their lifetime (e.g., cache blocks with zero reuse in Figure 5). Meanwhile, blocks with both high temporal and spatial locality make effective use of coarse-grained accesses, such that a simple bi-modal prediction is sufficient to greatly improve memory system performance and efficiency.

3.4.2 Microarchitecture

Our lightweight BGP microarchitecture determines whether each missed cache block has enough locality to warrant a coarse-grained fetch. We implement the storage of BGP using a bloom filter [37] to minimize the cost of tracking the multitude of cache blocks in the system. A bloom filter is a space-efficient probabilistic data structure that is used to test whether an element is a member of a set. It consists of a bitarray with m-bits and n-hash functions. An element is inserted (Figure 6(a)) into the bitarray with n different hashes of the element and setting the corresponding bits of the bitarray. Testing if an element belongs to the set (Figure 6(b)) is done by feeding it to the n hash functions and checking if all the corresponding bit positions are 1s. If any of the queried bits are 0, the element is definitely not a member of the set (true negative) while all 1s indicates either that the element actually was inserted to the set (true positive) or that there are many hash collisions with other elements of the set (false positive). The false positive rate of a bloom filter, accordingly, is determined by the number and type of hash functions chosen and the size of the bitarray. For the purpose of the BGP, a bloom filter is used to track the set of evicted blocks having low (or high) locality, using their respective block address as the inserted element.

In order to temporally degrade old insertions and maintain a certain amount of locality history, the locality predictor is implemented using a dual-bitarray microarchitecture as detailed in Figure 6. This dual-bitarray bloom filter uses two temporally overlapped bitarrays that are periodically cleared and swapped in order to eliminate interference due to stale locality data. Such structure has several implementation advantages. First, the dual-bitarray bloom filter allows for the removal of aging elements in an application-appropriate manner without resorting to more expensive bloom filter variants (such as a counting filter [38]). Also, the rolling history of the dual-bitarray naturally captures temporal locality information. Finally, because the dual-bitarray structure periodically resets, it allows us to tailor the default insertion/prediction mode (CG or FG) to dynamic phase behavior in order to reduce the false positive rate, as described below.

3.4.3 Prediction Mechanism

Figure 7 summarizes how bi-modal granularity prediction operates and when and how evicted blocks are inserted into the bloom filter. The BGP contains a default prediction (CG or FG) that determines what kind of evicted blocks are inserted into the filter (and the corresponding prediction upon a query to the filter). The CG/FG fetch decision is made by querying the bloom filter with the evicted block’s address—upon a miss, the querying cache block has the opposite locality characteristics to the blocks inserted into the bloom filter, so BGP grants the default prediction. For those queries that hit in the bloom filter, the BGP predicts the opposite of the default prediction (Figure 7(a)).

The BGP uses the number of sectors accessed as means to approximate the locality of cache block (rather than the number of accesses to the cache blocks) for simplicity in
design. When a cache block is evicted, accordingly, the associated sector used-bit information is examined to estimate the block’s locality—if the number of sectors accessed is below a pre-determined threshold ($TH_{FG}$), that block is estimated as having low locality and high locality otherwise (Figure 7(b)). This locality estimate is compared with the BGP’s current default prediction in order to determine whether the eviction should be inserted into the filter.

When the percentage of evicted cache blocks inserted into the bloom filter ($SKEW_{insert}$) is high, each filter will be filled quickly and the BGP will track little temporal history (Figure 6(c)). Inspired by the intuition of agree predictors [40], the BGP rotates the default prediction whenever $SKEW_{insert}$ is higher than a pre-determined threshold ($SKEW_{thresh}$) in order to avoid the bloom filter from being rapidly saturated by an overwhelming number of insertions (Figure 7(c)). Table 1 summarizes the microarchitectural parameters used for the baseline BGP configuration. The BGP bloom filter hash functions are inexpensive implemented in hardware by byte-slicing each evicted address and XOR-ing the slices together [39]. Overall, we observe that the prediction accuracy of BGP is relatively insensitive to these parameters, unless the bitarray size is less than 2K-bits or the refresh period is less than a quarter of the bitarray size.

### 3.4.4 Summary of the Benefits of BGP

The benefits of the proposed BGP are twofold. First, by granting FG accesses for only those accesses that have past history of low temporal locality, applications with good caching behavior (e.g., most of the sectors are utilized) or those with a working set fitting well in the cache (e.g., low miss rates and thus low evictions within a timeframe) are guaranteed to fetch data in CG-mode, maintaining the benefits of the CG-only memory system. Second, the bloom filter based BGP provides a cost-effective mechanism to determine the access granularity, as opposed to SPP-based schemes that require a separate PHT and complex control/update logic.

### 4. METHODOLOGY

#### 4.1 Simulation Model

We model LAMAR using GPGPU-Sim (version 3.2.0) [41, 42], which is a cycle-level performance simulator of a general purpose GPU architecture that supports CUDA 3.1 and its PTX ISA. The memory hierarchy of GPGPU-Sim is augmented with sectored L1/L2 caches and DrSim [43, 44], a detailed DRAM simulator that supports sub-ranked memory systems (Section 3). We configure our DRAM model to adhere to the GDDR5 specification [24], except for the bank-grouping effects (which are projected to be eliminated in future GDDR products [24, 45]). To demonstrate how the BGP is affected by limited hardware resources (e.g., dual 2K-bitarrays), we also simulate the SPP and BGP with unrealistically large histories (1M-entries); these impractical designs are denoted by SPP and $BGP_{inf}$ henceforth.

In general, the GPU simulator is configured to be similar to NVIDIA’s GTX480 [19] using the configuration file provided with GPGPU-Sim [46]. Key microarchitectural parameters of the baseline configuration are summarized in Table 2; we explicitly mention when deviating from these parameters for the sensitivity studies in Section 5.5.

#### 4.2 GDDR5 Power Model

We model DRAM power based on the Hynix GDDR5 specification [24] as summarized in the equation below. Our power model includes the background power, refresh power ($P_{REF}$), activation & precharge power ($P_{ACT+PRE}$), read power ($P_{RD}$) and write power ($P_{WR}$). The background power includes precharge standby power ($P_{PRE+STBY}$) and active standby power ($P_{ACT+STBY}$). Read and write power includes the power consumed by the DRAM bank ($P_{RD+WR}$) and by the IO pins ($P_{RD,JO}$).

$$P_{GDDR5} = \frac{P_{PRE+STBY} + P_{ACT+STBY} + P_{REF} + P_{ACT+PRE}}{P_{RD}} + \frac{P_{RD+WR} + P_{RD,JO} + P_{WR}}{P_{WR}}$$

#### 4.3 GPU Processor Power Modeling

This study is concerned primarily with the performance and efficiency of the memory hierarchy. To evaluate how LAMAR affects the overall system energy-efficiency, however, we model the GPU processor power using the analytical IPC-based power model suggested by Ahn et al. [25]. The peak power consumption of each SM is extracted using GPUWatch [47]. The leakage power of the system (including GPU processors and DRAM) is estimated to be 59 Watts. The peak dynamic
Table 3: Evaluated CUDA benchmarks. Avg$_{sec}$ refers to the average number of sectors accessed across all cache blocks.

power consumption per SM is estimated to be 9.5 Watts, out of which 2.3 Watts belongs to constant power that does not scale with IPC. Such simple IPC-based power modeling offers > 90% agreement with GPUWatch and is used to estimate the overall system efficiency in Section 5.4.

4.4 Benchmarks

LAMAR is evaluated with 32 benchmarks from Rodinia [1], CUDA-SDE [48], MapReduce [2], LonestarGPU [3], and the benchmarks provided with GPGPU-Sim [41]. We report the 20 applications (Table 3) that exhibit noticeable differences across different schemes for brevity. All benchmarks are simulated to completion, with the exception of SSSP, SP, PVC, SCLST, and FWT—due to the long simulation time of these applications, we execute them only up to the point where IPC is saturated with small variation among different iterations of the kernel. We categorize the 20 chosen benchmarks as either being FG-leaning or CG-leaning based on the average number of sectors accessed within all L1/L2 cache blocks (Figure 1) — applications that average more than two sectors per cache block are categorized as CG-leaning (and FG-leaning otherwise).

5. EVALUATION

This section evaluates LAMAR, considering its impact on cache efficiency, the improvements that LAMAR brings about in overall performance and energy-efficiency. We also discuss its sensitivity to key microarchitectural parameters and its implementation overheads. We compare five different GPU memory hierarchy designs: CG-only, FG-only, SPP, BGP$_{inf}$, and BGP, which are denoted by C/F/S/L/B, respectively, in all figures throughout this section. A LAMAR configuration based on static GDU decisions is equivalent to the best of CG-only and FG-only for each application. Note that we used the same dataset for both the profiling and measurement run.

5.1 Prediction Quality, Traffic, and Caching Efficiency

The GDU of LAMAR determines whether a cache block should be fetched in CG or in FG mode. It can therefore predict to: 1) correctly fetch sectors that are actually referenced (PRED$_{REF}$), and 2) incorrectly fetch sectors that are not referenced (PRED$_{NREF}$), and 3) incorrectly not fetch sectors that are referenced later (NPRED$_{REF}$). We therefore categorize each fetched sector as either being fetched on-demand from the upper level (DEMAND) or based on prediction (Figure 8)$^5$ The overall read/write traffic and the associated cache miss rates are depicted in Figure 9 and Figure 10. Overall, the FG-only scheme has the smallest off-chip traffic thanks to its conservative fetch decision. This reduced traffic, however, comes at the cost of a significant portion of sectors being NPRED$_{REF}$ with increased miss rates for some applications. NN, for instance, contains 65%/54% of its L1/L2 sectors being fetched NPRED$_{REF}$. Because these sectors would have been pre-fetched had the initial access been predicted as CG-fetches, memory access behavior and caching efficiency are degraded, potentially leading to performance penalties for certain applications (see Section 5.2 for details). CG-leaning applications generally contain less overfetched data (even with the CG-only scheme), with only 13%/3% more sectors fetched to L1/L2 compared to the FG-only scheme. For FG-leaning benchmarks, however, CG-only falls short by having 171% and 93% more L1/L2 read-in traffic than FG-only, most of which is due to the large number of mispredicted PRED$_{NREF}$ sectors.

Dynamically-driven LAMAR, on the other hand, is able to balance the benefits of both CG-only and FG-only schemes. All three LAMAR predictors can reduce off-chip traffic significantly without degrading the memory access behavior of CG-leaning applications. SPP is the least effective mechanism among the three, having 60%/72% more L1/L2 read-in sectors than FG-only, whereas BGP$_{inf}$ and BGP contain 20%/22% and 37%/47% more, respectively, thanks to the GPU-context appropriate prediction algorithm (Section 3.4).

In general, the CG-only scheme falls short by significantly overfetching data for FG-leaning applications while the FG-only scheme (despite its advantage in reducing off-chip traffic) disrupts the memory access behavior of several benchmarks. Accordingly, we observe that a static GDU configuration, preferably matching application characteristics (e.g., Avg$_{sec}$ provided by the profiler/autotuner), typically performs best in terms of overall bandwidth utilization, maximizing energy-efficiency. While less effective than the best-performing CG/FG-only scheme for each application, dynamically-driven LAMAR approximates the characteristics of the static GDU schemes, balancing the benefits of CG-fetches while reducing traffic when feasible. Compared to the BGP, SPP-based prediction lacks robustness and fails to effectively reduce off-chip traffic for SSSP, BFS1, SP, MUM and NW. However, SPP is still advantageous compared to a static memory hierarchy.

5.2 Performance

Figure 11 shows the overall speedup from adopting LAMAR memory schemes. In general, all LAMAR predictors provide significant benefit over the conventional CG-only memory system while executing FG-leaning applications thanks to more efficient utilization of the off-chip bandwidth, demonstrating a maximum 49% boost and an average 12–14% improvement in performance. LAMAR predictors also provides comparable performance to the CG-only scheme in executing CG-leaning applications—the biggest degradation is for MST (whose L1

$^5$Note that sectors requested from the L1 to L2 cache are interpreted as DEMAND from L2’s perspective, even though these sectors can be PRED$_{REF}$, PRED$_{NREF}$, and NPRED$_{REF}$ from the L1’s point of view.
Figure 10: The cache miss rates of the L1 (top) and L2 (bottom) caches.

caching efficiency is disrupted by LAMAR, lowering the IPC by 13\% with $BGP_{n,f}$. The static FG-only scheme adversely impacts 5 of the CG-leaning benchmarks, ranging from 4\% (SPROD) to 22\% (MST) degraded performance.

### 5.3 Impact on DRAM Power Efficiency

Correctly predicted FG-fetches reduce the number of read and write commands issued to DRAM. However, CG-fetches have the advantage of leveraging DRAM bank row locality by only having to open the corresponding bank row once. This is not the case for mispredicted FG-fetches ($NPRED\_REF$), which require re-opening the bank row at a later time and lead to additional activate/precharge (ACT/PRE) commands. Figure 12 illustrates how the reduction in off-chip traffic correlates with DRAM power consumption. Overall, the benefit of reduced read/write commands outweighs the overhead of increased ACT/PRE commands. For FG-leaning applications, FG-only achieves the largest average power reduction of 19\% (max 42\%) while SPP/$BGP_{n,f}/BGP$ obtain an average 1\%/13\%/8\% reduction (max 16\%/39\%/33\%), respectively.
Despite its low implementation cost, BGP is competitive with $BGP_{inf}$ and outweights SPP both in power reduction as well as Performance/Watt ($\text{Perf/Watt}$), with an average 27% increase in $\text{Perf/Watt}$ while SPP and $BGP_{inf}$ achieve an average 16%/34% improvement, respectively.

For CG-leaning applications, all LAMAR predictors perform comparable to the CG-only scheme whereas FG-only suffers from an average 5% degradation in $\text{Perf/Watt}$ (maximum 20% degradation).

5.4 System-Level Power Efficiency

We evaluate the system-level efficiency of different memory schemes by combining the DRAM power model (Section 5.3) with the IPC-based GPU processor power model (Section 4). Recent literature [47, 50] estimates that the memory system consumes approximately 5 to 45% of the overall GPU power, depending on the application. LAMAR mainly improves the energy-efficiency of the memory hierarchy, so the overall improvement in $\text{Perf/Watt}$ is less pronounced than its DRAM counterpart. Among FG-leaning applications, $BGP_{inf}$ and BGP obtains an average 18%/17% improvement in $\text{Perf/Watt}$ respectively. SPP helps the least among LAMAR predictors with an average 13% improvement in $\text{Perf/Watt}$. The FG-only mechanism, while achieving the highest average $\text{Perf/Watt}$ improvement (19%), struggles in executing CG-leaning applications and significantly degrades $\text{Perf/Watt}$ for MST, NN, and SRAD.

5.5 Sensitivity Study

We summarize LAMAR’s sensitivity to key parameters in this subsection. Due to space limitations, we mainly discuss the effectiveness of LAMAR on FG-leaning applications.

5.5.1 Cache Capacity

As shown in Figure 14(a), DRAM traffic is generally reduced with larger on-chip caches (and vice versa for smaller caches) thanks to better caching efficiency. The benefits of LAMAR are still maintained across all FG-leaning applications and the relative reduction in traffic (compared to each configuration’s CG-only scheme) is more pronounced with smaller caches (e.g., IIX, BFS1, SSC, BFS2, WP). BGP, for instance, provides an average 32%/33%/17% reduction in traffic with the three cache size configurations.

5.5.2 Cache Block Size

With a larger L2 cache block (256B), the baseline CG-only scheme is likely to overfetch even more off-chip sectors and to suffer from severe bandwidth under-utilization. Such behavior is illustrated in Figure 14(b) where a 256B configuration of CG-only uses an average 96% more memory traffic than the baseline. The benefits of LAMAR, accordingly, are much more evident under the 256B configuration, where BGP reduces off-chip traffic by an average of 58% compared to the 33% reduction using the baseline cache block size.

5.5.3 Larger Sector Size

To demonstrate the benefits of LAMAR with minimal changes to the GPU system, we evaluate the proposed mechanisms without a sub-ranked off-chip memory system. A conventional GDDR5-based memory system provides a minimum access granularity of 64-bytes (Figure 2), so we evaluate LAMAR with a 64-byte sector size and minimum access granularity. As depicted in Figure 14(c), the benefit of LAMAR is reduced from an average 33% traffic reduction to 20% under BGP due to the lack of sub-ranking.

5.5.4 Thread-Level Parallelism

Recent literature [36, 10] shows that throughput processors make poor use of data caches, due to the high cache access intensity and the resulting low per-thread cache capacity. To this end, previous work makes the warp scheduler cache-conscious [10] such that the number of warps able to access the cache are dynamically reduced (hence throttling thread-level parallelism [TLP] available at the SM) if the cache is thrashing. Such cache-conscious warp scheduling (CCWS) is therefore only effective when the application is both cache-sensitive and is thrashing. While LAMAR focuses on wasted-transfers due to granularity mismatches in the system and is orthogonal to CCWS, we nonetheless evaluate the effectiveness of LAMAR on top of this technique. Since CCWS is effectively a dynamic mechanism that approximates the statically chosen optimal level of TLP, we experiment LAMAR on top of CCWS as detailed in Figure 15. As depicted, three of the 20 applications we study (IIX, MUM, SCLST) benefit from TLP throttling and LAMAR remains effective in the presence of TLP tuning.

5.5.5 Miscellaneous

As mentioned in Section 3.4, the prediction quality of the baseline BGP microarchitecture is relatively robust with bitarray sizes larger than 2K-bits. Performance is improved by 2% to 7% with a 4K-bitarray, but saturates when going from 4K-bits to 8K-bits. Changing $TH_{GDU}$ and $SKEW_{thres}$ (Figure 7) also affects off-chip traffic and performance, but overall trends remain similar to the analysis discussed throughout this section (so long as $SKEW_{thres}$ is above 0.7 and $TH_{GDU}$ is less than three sectors).

5.6 Implementation Overhead

LAMAR is implemented using a sector cache and a sub-ranked memory system, the overheads of which are well established in previous literature [25, 26, 27, 28, 29, 30]. In addition, each cache partition is augmented with a GDU. Static GDU configurations require no additional hardware, but necessitate profiler/autotuner support to provide recommended granularity information. We leave further exploration of identifying the optimal granularity to future work.

For dynamic GDU schemes, the proposed BGP microarchitecture (using a dual-bitarray bloom filter) requires 1) 4K-bits of storage per GDU, 2) 6 sets of XOR logic gates for the hash functions, and 3) control logic to insert/test the membership of the bloom filter (Table 1).
Figure 12: A breakdown of DRAM power (Watt, left axis) and the corresponding Perf/Watt (normalized to CG-only, right axis).

Figure 13: The system power consumption (Watt, left axis) and the corresponding Perf/Watt (normalized to CG-only, right axis). Note that the range of the upper plot is 0.8–1.8, whereas it is only 0.7–1.2 for the bottom plot.

6. DISCUSSION

6.1 LAMAR on Future Memory Technologies

In order to be concrete and to allow a detailed evaluation, we use GDDR5 as our memory technology. Future GPUs, however, may use evolving memory interface standards that utilize 3D packaging technology, such as the Hybrid Memory Cube (HMC) [51] or High-Bandwidth Memory (HBM) [52]. Although these interfaces are likely to offer much higher bandwidth than GDDR5, GPU arithmetic performance will increase as well, such that effectively utilizing memory throughput will remain critical to performance and efficiency. In fact, capacity-to-bandwidth ratio is likely to increase with the use of HMC packages—this implies that bandwidth utilization will increase in importance, amplifying the potential benefits of LAMAR. The proposed access granularity for these interfaces is also similar to that of GDDR5 devices today, with HMC proposing an access granularity of 32 – 256-bytes and with HBM likely to use a 32-byte granularity similar to the WideIO standard [53]. Thus, the opportunity and policies we propose for LAMAR should generally apply equally well.

With 3D packaging, it is likely that the memory controller will be partitioned between the processor and the DRAM die stacks: scheduling is likely to remain close to the processor, where knowledge of priorities and requests is readily available, while implementation of the DRAM access protocol will be relegated to the controller within each stack [51]. This partitioning will require a re-design of how LAMAR controls the memory modules (owing to the fact that sub-ranks are essentially internalized and hidden within each stack). Because scheduling is still delegated to the processor, LAMAR will have to be modified to account for sending the appropriate request packets to maximize transfer efficiency. We will develop and analyze such designs in future work.

6.2 Error Correction

Current GPUs support error correction with error correcting codes (ECC). While the details of the memory protection schemes in industry are not publicly known, one way of flexibly supporting error correction without dedicated DRAM chips is through virtualized ECC [54]. The approach taken by LAMAR is amenable to such error correction, in a similar manner to prior work [18, 32].

6.3 Alternative FG Cache Management

LAMAR uses a simple sector cache to manage FG data in the on-chip cache hierarchy, as our current study focuses on
The efficiency management of off-chip data for irregular GPU applications. However, alternative FG cache management schemes exist, such as the decoupled sectored cache [55], pool-of-sectors cache [56], or the spatio/temporal cache [57]. Such more advanced cache architectures could be adopted to increase the effective capacity of the cache for irregular applications. Some irregular applications are very sensitive to the (typically limited) on-chip storage capacity, such that these alternative caches could significantly increase performance. Optimization of the on-chip portion of LAMAR is left for future study.

6.4 Other Dynamic Bloom-Filter Mechanisms

The BGP incorporates two temporally-separated Bloom filters to support the aging of membership data and to allow space-efficient operation with a dynamic stream of accesses. The temporal aging of Bloom filter entries for dynamic data has been addressed by Deng and Rafiei [58] by associating a slowly degrading count with each storage cell. However, this design makes inefficient use of storage and is unlikely to perform competitively with the BGP. The concept of maintaining and swapping two temporally-separated Bloom filters has been previously employed in software for filtering dynamic data [59, 60, 61]. BGP is the first application of such a scheme to memory access granularity prediction in hardware and is unique in its implementation and default prediction inverting algorithm. Yoon [62] recently proposed an alternate two-buffer algorithm for filtering dynamic data that could provide modest accuracy benefits for the BGP. Incorporating and analyzing this algorithm (along with BGP’s novel default prediction inversion algorithm) is left for future work.

7. CONCLUSIONS

The increasing popularity of general-purpose GPU programming and the growing irregularity of throughput-oriented programs necessitate a fine-grained GPU memory system. Meanwhile, the continuing need for the high-performance acceleration of regular, well structured programs and graphical workloads make coarse-grained memory accesses compulsory as well. This paper proposes LAMAR, an adaptive and reactive hardware-only memory scheme for GPUs and...
throughput-oriented processors that achieve superior efficiency across a range of general-purpose GPU applications. By dynamically predicting the temporal and spatial locality of memory accesses, LAMAR mitigates the deficiencies of static-granularity memory systems and prior mixed-granularity memory schemes for control-intensive CPUs. In addition, the hardware required for LAMAR is simple and non-intrusive enough to be readily implemented in a many-core GPU and its adoption requires no programmer intervention. Our results show that LAMAR provides an average 14% increase in performance (max 49%), 33% reduction in average off-chip traffic (max 64%), and an average 17% improvement in system-level energy-efficiency (max 47%).

8. ACKNOWLEDGMENTS

We would like to thank the developers of GPGPU-Sim and the anonymous reviewers, who provided excellent feedback for preparing the final version of this paper. Special thanks to Min Kyu Jeong at Oracle Labs for answering numerous questions regarding the use of DrSim. This work is supported in part by the National Science Foundation (Grant #0954107) and Intel Labs URO for the Memory Hierarchy Innovations program.
